Czy możemy zrozumieć chmury nie rozumując turbulencji?

Szymon Malinowski

KMMF, 12.04.2012
Turbulence: what is it?

**turbulence** —

1. *Irregular fluctuations occurring in fluid motions.* It is characteristic of turbulence that the fluctuations occur in all three velocity components and are unpredictable in detail; however, statistically distinct properties of the turbulence can be identified and profitably analyzed. Turbulence exhibits a broad range of spatial and temporal scales resulting in efficient mixing of fluid properties.

2. *Random and continuously changing air motions that are superposed on the mean motion of the air.*

_Glossary of Meteorology, American Meteorological Society_

**turbulence** — In fluid mechanics, _a flow condition (see turbulent flow) in which local speed and pressure change unpredictably as an average flow is maintained._

**atmospheric turbulence** — _small-scale, irregular air motions characterized by winds that vary in speed and direction._ Turbulence is important because it mixes and churns the atmosphere and causes water vapour, smoke, and other substances, as well as energy, to become distributed both vertically and horizontally.

_Britannica Online_
Cloud: what is it?

Cloud – A visible aggregate of minute water droplets and/or ice particles in the atmosphere above the earth’s surface

*Glossary of Meteorology, American Meteorological Society*

Cloud – any visible mass of water droplets, or ice crystals, or a mixture of both that is suspended in the air, usually at a considerable height

*Britannica Online*

What is the typical size of aerosol and cloud particles?
- From a few nanometers: a few molecules condensed
- To a few centimeters: hailstones

**Measurable parameters from in-situ observations**

- Particle size: $\mu m, mm, cm \ldots \ldots 1\mu m<D<10cm$
- Number Concentration: $cm^{-3}; l^{-1}; m^{-3} \ldots \ldots 1000cm^{-3}<N<1m^{-3}$
- Extinction Coefficient: $km^{-1} \ldots \ldots 100km^{-1}<\beta<0.01 \ km^{-1}$
- Water Content: $g/m^3 \ldots \ldots 10g/m^3<W<0.0001g/m^3$

Figure 6  Cartoon of trade-wind boundary layer from large-eddy simulation. Heights of cloud base, level of maximum $\theta_l$ gradient (inversion height), and maximum cloud penetration depth are indicated, as are subcloud layer and inversion-level values of thermodynamic quantities. Cloud water contents are averaged over cloudy points only, with adiabatic liquid water contents indicated by the dash-dot line. The far right panel shows cloud fraction, which maximizes near cloud base at just over 5%.

Stevens, 2005
Fig. 14. Schematic model of a cumulus cloud showing a shear thermal that has ascended from cloud base. Continuous entrainment into the surface of the thermal erodes the core, and the remaining undiluted core region continues its ascent, leaving a turbulent of mixed air behind it. See text for further discussion.

Fig. 17. Wind velocity (i) and liquid water content (ii) for three KA penetrations from 1625 to 1633 MDT in the 19 July 1981 cloud: (a) 472 mb, (b) 514 mb and (c) 527 mb. The wind vectors are formed from the vertical wind and the wind along the flight path and are drawn to scale.

Conceptual sketch of cumulus and supporting data.

Blyth et al., 1988
**TKE dissipation in small cumulus clouds**

The following parameters characterize warm turbulent clouds and give some indication of their variability.

**Mean $\varepsilon$, can vary** from $\sim 10 \text{ cm}^2\text{s}^{-3}$ in stratiform clouds to $\sim 2000 \text{ cm}^2\text{s}^{-3}$ in cumulonimbus clouds (e.g. Caughey et al., 1982; MacPherson and Isaac, 1977).

$R_\lambda$, *varies* from $\sim 5000$ in stratiform clouds to $\sim 20,000$ in strong deep convective clouds (e.g. Shaw, 2003; Khain et al., 2007);

$\varepsilon \sim 3 \text{ cm}^2\text{s}^{-3}$ and $R_\lambda \sim 5000$ for stratocumulus (Siebert et al., 2010)

$\varepsilon \approx \sim 30 \text{ cm}^2\text{s}^{-3}$ and $R_\lambda \sim 4 \times 10^4$ for small cumulus (Siebert et al., 2006).

The **maximum LWC** are in convective clouds with very strong updrafts and not exceed $4–5 \text{ g m}^{-3}$; *typically* in cumulus $0.1–2 \text{ g m}^{-3}$ depending on the stage of development (Pruppacher and Klett, 1997, §2.1.3).

Most estimates of cloud parameters come from a limited number of measurements at low resolution; only recently (Siebert et al., 2006; Siebert et al., 2010) have higher-resolution ($\sim 20\text{cm}$) measurements.

CCN activation: Kohler theory

\[ S = \frac{e}{e_s} \approx 1 + \frac{A}{r} - \frac{B}{r^3} \] (2)

where \( A = \frac{2M_w \sigma_w}{RT \rho_w} \) and \( B = \frac{v m_s M_w}{M_s (4/3 \pi \rho_w)} \), where \( v \) is the number of dissociated ions per solute molecule, \( m_s \) is the solute mass and subscripts \( s \) and \( w \) relate to solute and water properties, respectively. The term in \( A \) is denoted the Kelvin or curvature term, and that in \( B \), the Raoult or solute term.

Fig. 1. The Kohler equation can be envisaged as the competition between the curvature (Kelvin) and solute (Raoult) terms.

Fig. 3. Activation curves for a range of dry diameter of salt ((NH\(_4\))\(_2\) SO\(_4\) – solid, NaCl – dashed) particles (red, green and blue curves) and for 200 nm particles containing 50% by mass insoluble core (magenta).
Fig. 4. Simulation showing the change in droplet radius with height in a simulation initialized with an ammonium sulphate aerosol with a geometric mean diameter of 140nm, a geometric standard deviation, $\sigma$ of 1.7 and aerosol number concentration of 300 cm$^{-3}$ (corresponding to a total mass loading of 0.76µgm$^{-3}$). The simulation was started at an RH of 95% at 1000 m. Solid lines represent selected aerosol size classes. The dashed line is the saturation ratio.

What is rain?

**rain** — Precipitation in the form of liquid water drops that have diameters greater than 0.5 mm, or, if widely scattered, the drops may be smaller.

The only other form of liquid precipitation, drizzle, is to be distinguished from rain in that drizzle drops are generally less than 0.5 mm in diameter, are very much more numerous, and reduce visibility much more than does light rain.

**warm rain** — Rain formed from a cloud having temperatures at all levels above 0°C (32°F), and resulting from the droplet coalescence process.

_Glossary of Meteorology, American Meteorological Society_

**rain** — Precipitation of liquid water drops with diameters greater than 0.5 mm (0.02 inch). When the drops are smaller, the precipitation is usually called drizzle. See also precipitation.

Figure 5: Distribution of droplets with gaussian spectrum after 2.5 turnover times of the vortex. Initial distribution was spatially uniform.
Example: motion of droplets in small-scale vortical structure in fluid.

**Figure 1.** - Particles with different inertia released at the same position and inside a small scale vortical structure of the fluid. The neutrally buoyant particles (red) remain strongly trapped, while particles with higher and higher inertia, respectively green, blue, yellow etc, are less and less sensitive to small scale vorticity.

F. Toschi
First experimental evidence of droplets expelled from vortex tubes in real clouds – Bodenschatz, Xu, Malinowski et al., 2011, Zugspitze cloud campaign – not published yet....
Length scales associated with condensational growth of droplets.

The condensational growth of droplets is characterized by vapor pressure gradients and temperature gradients.

When the growth of an ensemble of droplets in turbulent air is considered, the temperature and the moisture fields away from the droplet may vary considerably and the concept of ambient conditions becomes vague. The 'boundary conditions' imposed between droplets may depend on both the spatial distribution of droplets as well as on the supersaturation and temperature fields.

Vaillancourt et al. (2001) defined the ambient conditions to be the moisture and temperature fields in the vicinity of a given droplet averaged over the volume defined by the mean distance between droplets (so-called point-particle approach to describe the evolution of the droplet phase (adopted by Celani et al., 2007; Lanotte et al. 2009)).

Most studies of the growth of an ensemble of droplets neglect the direct thermodynamic interaction between droplets, arguing that the mean distance between cloud droplets ($\sim 2\text{mm for a typical concentration of } 100 \text{ cm}^{-3}$) is at least an order of magnitude larger than the distance affected by the variation of moisture and temperature due to cloud droplet growth.
Time scales associated with condensational growth of droplets

Scale of diffusional growth of an isolated droplet and in typical conditions is less than $1 \times 10^{-3}$ s.

Another time scale occurs when the boundary conditions for water-vapor concentration and temperature at the surface of the droplet are not assumed constant. During condensation water vapor diffuses onto the surface of the droplet, latent heat is released, and consequently the surface temperature (the psychometric temperature) of the droplet changes. The relaxation time associated with this process lies typically between $5 \times 10^{-4}$ s and $1 \times 10^{-2}$ s for droplet radii between 5 µm and 25 µm) SLOWEST!!!

Vaillancourt et al. (2001) showed that, for $a=20$ µm and $\varepsilon=100$ cm$^2$ s$^{-3}$, the ratio of this time scale to fastest time scale associated with changes to the ambient conditions due to turbulence (either $\tau_\eta$ or $\tau_\nu$) is much less than one and the assumption of a steady-state distribution of water-vapor concentration and temperature is valid.

Numerical simulations by Celani et al. (2005, 2007), Lanotte et al. (2009), Sidin et al., (2009) suggest that cloud droplet spectra can be broadened during condensation, which is different from simulations of Vaillancourt et al. (2002) and from the measurements in real clouds (as we can interpret them).
Collisions, coalescence and turbulence

The collision and coalescence of droplets in a turbulent flow are governed by
(i) geometric collisions due to droplet-turbulence interactions;
(ii) collision efficiency due to droplet-droplet interactions
(iii) coalescence efficiency due to droplet surface properties.

In practice, it is difficult to distinguish between collision and coalescence and the experimentally measurable quantity is collection efficiency defined as the ratio of the actual cross-section for droplet coalescence to the geometric cross-section.

Geometric collisions
DNS results (e.g. Franklin et al. 2007; Ayala et al. 2008a) show that turbulence can increase the collision kernel relative to the case of stagnant air by two effects:

droplet relative velocity
droplet clustering.

Turbulence may also affect the droplet relative velocity through preferential sweeping whereby droplets bias their downward trajectories towards regions of higher turbulence thus increasing their terminal velocities relative to still air.

Caustics (sling effect) are also considered (e.g. Falkovich and Pumir, 2007)
In multidisperse suspensions, $|w_{12}|$ is always larger than its monodisperse counterpart.

This can be understood by considering a limiting case of monodisperse suspension, in the absence of gravity. For low St, velocities of equally sized droplets are strongly correlated, both with the fluid and each other. As St increases, the correlation of the droplets with the flow and each other decreases and $|w_{12}|$ increases. However, for St>>1, droplets respond slowly to changes in the fluid velocity and $|w_{12}|$ decreases.

For multidisperse droplets, the velocities of the droplets decorrelate more rapidly than the equivalent monodisperse cases since the droplets with different inertia respond differently to changes in the flow.

Figure 2. The ratio of a typical turbulent collision kernel to a purely gravitational collision kernel (Grabowski and Wang, 2009). The ratio on the 45° degree line is undefined due to the zero value of the gravitational kernel. The ratio is essentially one when droplets are greater than 100 μm. The flow dissipation rates are 400 cm$^2$ s$^{-3}$ and 100 cm$^2$ s$^{-3}$ in the upper-left and lower-right part of the figure respectively.
However.....in situ measurements...

With the **improved** size and spatial resolutions of the Fast-FSSP measurements it has been possible to identify **very narrow spectra** in most of the cloud traverses...

These spectra are **much narrower than previously measured with the standard probe**.

The regions of narrow spectra show characteristics close to the adiabatic reference, such as LWC values slightly lower than the adiabatic value at that level and values of droplet concentration close to the maximum value within the cloud traverse. **The spectra observed in these regions are narrow but still broader than the adiabatic reference**.

The high concentration densities of droplets with diameter smaller than the mode can be attributed to partial evaporation of some droplets resulting from the mixing with dry air. The occurrence of this process is attested by the slightly subadiabatic values of LWC.

Chaumat and Brenguier, 2001
Short summary of clustering and collisions:

Observations of droplet clustering in real clouds remain ambiguous which has led some authors to question its importance in real clouds.

Moreover, DNS of sedimenting droplets has shown that turbulent enhancement of collision rates occurs primarily through changes to the droplet relative velocity and the collision efficiency.

Nevertheless, some argue that the vortex tubes that are associated with small-scale turbulence at high Reynolds numbers persist for long and droplets with a considerable range of St are able to spin out of the vortex.

The importance of intermittency in potentially increasing droplet clustering has also been raised by Falkovich et al. (2002) who based on theoretical arguments claim that clustering can increase collisions by a factor of 10.

Without a clear theoretical basis for the $R_\lambda$-dependence of clustering, which will remain valid in the large-$R_\lambda$ limit, it is likely that these arguments will continue.
Homogenenous vs. Inhomogeneous mixing (Baker and Latham 1979) in numerical simulations of small-scale mixing

\[ \tau_{\text{mix}} \equiv \frac{L}{U(L)} \sim \left( \frac{L^2}{\epsilon} \right)^{1/3} \]

\[ \tau_{\text{evap}} \equiv \tau \left( \frac{dr}{dt} \right)^{-1} = \frac{r^2}{A(1 - RH)} \]

In the homogeneous mixing scenario, the number of droplets does not change and the mean droplet size decreases. In the extreme inhomogeneous mixing scenario, droplets from a fraction of the cloudy volume evaporate completely to bring the mixture to saturation, and the droplets from the rest of the cloudy volume are dispersed over the combined volumes without changing their size.

If the droplet evaporation time scale is much larger than the time scale of turbulent homogenization, the mixing is expected to be close to homogeneous. In the opposite limit (i.e., the droplet evaporation time scale much smaller than the time scale of turbulent homogenization), the mixing is supposed to be close to the extremely inhomogeneous.
Small-scale turbulence/rain formation in clouds – a subgrid scale process
   a) inadequate measurement capabilities 
      (resolution problem, different sampling volumes of various sensors)
   b) subgrid-scale processes in cloud resolving and LES simulations.

Closing the gap in resolved scales
   a) DNS and particles in turbulence;
   b) laboratory experiments with particle tracking and collisions.
   c) in situ efforts.

Issues
   a) (almost) no combined measurements of microphysics, turbulence and dynamics in small-scales;
   b) problems with the statistical interpretation of data from measurements;
   c) unclear subgrid-scale parameterizations in cloud simulations.

In the following: my efforts to address issues....
Examples of the cloud edge in 1000 Hz temperature (thin line) and LWC (thick line) records. Sharp jumps in LWC and temperature at distances of the order of 10 cm (data resolution) are currently observed. Notice a shift between the temperature and LWC records resulting from the 6 m separation between the instruments and the low pitch angle of the aircraft with respect to the cloud clear air interface.

Haman et al., 2007
From the top to the bottom: successive ‘blow ups’ of 10 kHz temperature records showing self-similar structures – filaments of significantly different temperatures separated by narrow interfaces. The bottom panel presents the evidence for filaments of thickness of the order of 10 cm as well as for the steep gradients of temperature. Notice that UFT-F in its present configuration and signal conditioning (low-pass filtering) is still too slow to resolve adequately all interesting small-scale features of the temperature field.

\((u_{\text{hor}})^2 / (u_3)^2 = 0.52 \pm 0.07\)
Scatter plot of the slope of the mixing line on the $r - N$ diagram versus the ratio between the turbulent mixing and the droplet evaporation time scales. Each data point represents analysis of instantaneous DNS data as explained in text, with triangles (circles) depicting data points with the mixing time scale calculated using TKE (enstrophy). The solid line is the proposed relationship to be used in subgrid-scale modeling.
Clouds are dispersions of drops and ice particles embedded in and interacting with a complex turbulent flow. They are highly nonstationary, inhomogeneous, and intermittent, and embody an enormous range of spatial and temporal scales. Strong couplings across those scales between turbulent fluid dynamics and microphysical processes are integral to cloud evolution.

Turbulence drives entrainment, stirring, and mixing in clouds, resulting in strong fluctuations in temperature, humidity, aerosol concentration, and cloud particle growth and decay. It couples to phase transition processes (such as nucleation, condensation, and freezing) as well as particle collisions and breakup. All these processes feed back on the turbulent flow by buoyancy and drag forces and affect cloud dynamical processes up to the largest scales.

The last decades have seen the emergence of new views into the “inner workings” of both clouds and turbulent flows. For example, high-resolution measurements of temperature, liquid water content, aerosol physical and chemical properties, and airflow reveal fascinating small-scale cloud structures, invisible with earlier technology. Laboratory experiments and numerical simulations are allowing us to study details of cloud microphysics, the fine structure of turbulence, turbulent Lagrangian dynamics, interactions and collisions between droplets. Scale-resolving simulations merging computational methods from both cloud and turbulence communities are yielding new insights into the wide variety of circulation regimes.

These new tools, experimental and computational, have begun to make it possible to explore the full complexity of microphysical and fluid-dynamical interactions within clouds.

We can now begin to address:

➢ How does turbulence influence phase transition processes like condensation, evaporation, activation, and freezing taking place inside clouds?
➢ How does turbulence influence particle-particle interactions like collisions, coalescence efficiencies, ice aggregation, and drop- or ice-breakup?
➢ How do microphysical processes feed back on the turbulence through latent-heat release, energy injection at small scales, and buoyancy reversal?
➢ How do small scale processes propagate to and couple to the larger scales, such as, cloud dynamics, precipitation formation, and radiative properties?
